Skin Cancer Prevention and Early Detection

Skin cancer is the most common of all cancer types. More than 3.5 million skin cancers are diagnosed each year in the United States. That's more than all other cancers combined. The number of skin cancer cases has been going up over the past few decades.

The good news is that you can do a lot to protect yourself and your family from skin cancer, or to catch it early enough so that it can be treated effectively. Most skin cancers are caused by too much exposure to ultraviolet (UV) rays. Most of this exposure comes from the sun, but some may come from man-made sources, such as indoor tanning beds.

You don’t need any x-rays or blood tests to find skin cancer early, – just your eyes and a mirror. If you have skin cancer, finding it early is the best way to make sure it can be treated effectively.

What is skin cancer?

There are 2 main types of skin cancers: keratinocyte cancers (basal and squamous cell skin cancers) and melanomas.

- Basal and squamous cell skin cancers are by far the most common cancers of the skin. They develop from cells called keratinocytes, the most common cells in the skin.

- Melanomas are cancers that develop from melanocytes, the cells that make the brown pigment that gives skin its color. Melanocytes can also form benign (non-cancerous) growths called moles.

There are other types of skin cancers as well, but they are much less common.

It is important for doctors to tell these types of skin cancer apart, because they are treated differently. It is also important for you to know what melanomas and basal and squamous cell skin cancers look like. This may help you find them at the earliest possible stage, when they are cured most easily.

Basal and squamous cell cancers (keratinocyte cancers)

Basal cell and squamous cell cancers are the most common cancers of the skin. They develop from skin cells called keratinocytes. Both basal cell and squamous cell cancers are found mainly on
parts of the body exposed to the sun, such as the head and neck. These cancers are strongly related to the amount of sun exposure a person has had.

Basal and squamous cell cancers are much less likely than melanomas to spread to other parts of the body and become life threatening. Still, it is important to find and treat them early. If left untreated, they can grow quite large and invade into nearby tissues and organs, causing scarring, deformity, or even loss of function in some parts of the body. Some of these cancers (especially squamous cell cancers) may even spread if not treated, and rarely they can be fatal.

These cancers are discussed in more detail in our document, *Skin Cancer: Basal and Squamous Cell*.

**Melanomas**

Melanomas can occur anywhere on the body, but are more likely to start in certain locations. The trunk (chest and back) is the most common site in men. In women, the legs are the most common site. The neck and face are other common sites.

Melanomas are not as common as basal cell and squamous cell skin cancers, but they can be far more serious. Like basal cell and squamous cell cancers, melanoma is almost always curable in its early stages. But if left alone, melanoma is much more likely to spread to other parts of the body, where it can be very hard to treat.

Melanomas are discussed in more detail in our document, *Melanoma Skin Cancer*.

**What is ultraviolet (UV) radiation?**

Ultraviolet (UV) radiation is a major risk factor for most skin cancers. Sunlight is the main source of UV rays, which can damage the DNA in your skin cells. Tanning lamps and beds are also sources of UV rays. People who get a lot of exposure to light from these sources are at greater risk for skin cancer.

Ultraviolet radiation has 3 wavelength ranges:

- **UVA rays** age cells and can damage cells’ DNA. They are linked to long-term skin damage such as wrinkles, but are also thought to play a role in some skin cancers.
- **UVB rays** can directly damage DNA, and are the main rays that cause sunburns. They are also thought to cause most skin cancers.
- **UVC rays** don’t get through our atmosphere and therefore are not in sunlight. They are not normally a cause of skin cancer.

UVA and UVB rays make up only a very small portion of the sun’s rays, but they are the main cause of the sun’s damaging effects on the skin. UV rays damage the DNA of skin cells. Skin cancers begin when this damage affects the DNA of genes that control skin cell growth. Both UVA and UVB rays damage skin and cause skin cancer. UVB rays are a more potent cause of at least some skin cancers, but based on what is known today, there are no safe UV rays.

The amount of UV exposure a person gets depends on the strength of the rays, the length of time the skin is exposed, and whether the skin is protected with clothing or sunscreen.
Skin cancers are one result of getting too much sun, but there are other effects as well. Sunburn and tanning are the short-term results of too much exposure to UV rays, and are signs of skin damage. Long-term exposure can cause prematurely aged skin, wrinkles, loss of skin elasticity, dark patches (lentigos, sometimes called *age spots* or *liver spots*), and pre-cancerous skin changes (such as dry, scaly, rough patches called *actinic keratoses*).

The sun’s UV rays also increase a person’s risk of cataracts and certain other eye problems and can suppress the skin’s immune system. Darker-skinned people are generally less likely to get skin cancer than light-skinned people, but they can still get cataracts and suppression of the skin’s immune system.

### The UV Index

The amount of UV light reaching the ground in any given place depends on a number of factors, including the time of day, time of year, elevation, and cloud cover. To help people better understand the intensity of UV light in their area on a given day, the National Weather Service and the Environmental Protection Agency (EPA) have developed the UV Index. The UV Index number, on a scale from 1 to 11+, is a measure of the strength of the UV rays reaching the ground during an hour around noon. The higher the number, the greater the exposure to UV rays, and the higher the chance of sunburn and skin damage that could ultimately lead to skin cancer.

The UV Index is given daily for regions throughout the country. Many newspaper, television, and online weather forecasts include the projected UV Index for the following day. Further information about the UV Index, as well as your local UV Index forecast, is available on the EPA’s web site at [www.epa.gov/sunwise/uvindex.html](http://www.epa.gov/sunwise/uvindex.html). As with any forecast, local changes in cloud cover and other factors may change the actual UV levels experienced.

### Are some people more likely to get sun damage?

Everyone’s skin and eyes can be affected by the sun and other forms of UV rays. People with light skin are much more likely to have sun damage, but darker-skinned people, including African Americans and Hispanic Americans, also can be affected.

The skin tans when it absorbs UV radiation. The tan is caused by an increase in the activity and number of melanocytes, the cells that make the pigment melanin. Melanin helps to block out damaging UV rays up to a point, which is why people with naturally darker skin are less likely to get sunburned, while people with lighter skin are more likely to burn. Sunburns are thought to increase your risk of skin cancer, including melanoma. But UV exposure can raise skin cancer risk even without causing sunburn.

Aside from skin tone, other factors can also affect your risk of damage from UV light. You need to be especially careful in the sun if you:

- Had skin cancer before
- Have a family history of skin cancer, especially melanoma
- Have lots of moles, irregular moles, or large moles
- Have freckles and burn before tanning
• Have fair skin, blue or green eyes, or blond, red, or light brown hair
• Live or vacation at high altitudes (the strength of UV rays increases the higher up you are)
• Live or vacation in tropical or subtropical climates
• Work indoors all week and then get intense sun exposure on weekends
• Spend a lot of time outdoors
• Have certain autoimmune diseases, such as systemic lupus erythematosus (SLE, or “lupus”)
• Have had an organ transplant
• Take medicines that lower your immunity
• Take medicines that make your skin more sensitive to sunlight

Ask your doctor, nurse, or pharmacist if you are taking any medicines that could increase your sensitivity to sunlight.

**How do I protect myself from UV rays?**

You don’t have to avoid sunlight completely, and it would be unwise to reduce your level of activity by avoiding the outdoors, because physical activity is important for good health. But too much sunlight can be harmful. There are some steps you can take to limit your exposure to UV rays.

Some people think about sun protection only when they spend a day at the lake, beach, or pool. But sun exposure adds up day after day, and it happens every time you are in the sun.

Simply staying in the shade is one of the best ways to limit your UV exposure. If you are going to be in the sun, “Slip! Slop! Slap! and Wrap” is a catch phrase that can help you remember some of the key steps you can take to protect yourself from UV rays:

• Slip on a shirt.
• Slop on sunscreen.
• Slap on a hat.
• Wrap on sunglasses to protect the eyes and sensitive skin around them.

**Seek shade**

An obvious but very important way to limit your exposure to UV light is to avoid being outdoors in direct sunlight too long. This is particularly important between the hours of 10 am and 4 pm, when UV light is strongest. If you are unsure about the strength of the sun’s rays, use the shadow test: if your shadow is shorter than you are, the sun’s rays are the strongest, and it is important to protect yourself.

UV rays reach the ground all year, even on hazy days, but the strength of UV rays can be different based on the time of year and other factors. The UV rays become more intense in the spring, even
before temperatures get warmer. People in some areas may get sunburned when the weather is still cool because they may not think about protecting themselves if it’s not hot out. Be especially careful on the beach or in areas with snow because sand, water, and snow reflect sunlight, increasing the amount of UV radiation you receive. UV rays can also reach below the water’s surface, so you can still get a burn even if you’re in the water and feeling cool.

Some UV rays can also pass through windows. Typical car, home, and office windows block most of the UVB rays but a smaller portion of UVA rays, so even if you don’t feel you’re getting burned your skin may still get some damage. Tinted windows help block more UVA rays, but this depends on the type of tinting. UV radiation that comes through windows probably doesn’t pose a great risk to most people unless they spend long periods of time close to a window that receives direct sunlight.

If you plan to be outdoors, you may want to check the UV Index for your area first. The UV Index usually can be found in local newspaper, TV, radio, and online forecasts. It is also available on the EPA’s web site at www.epa.gov/sunwise/uvindex.html and in a variety of smartphone apps.

**Protect your skin with clothing**

When you are out in the sun, wear clothing to protect as much skin as possible. Clothes provide different levels of UV protection, depending on many factors. Long-sleeved shirts, long pants, or long skirts cover the most skin and are the most protective. Dark colors generally provide more protection than light colors. A tightly woven fabric protects better than loosely woven clothing. Dry fabric is generally more protective than wet fabric.

Be aware that covering up doesn’t block out all UV rays. If you can see light through a fabric, UV rays can get through, too.

Some companies now make clothing that is lightweight, comfortable, and protects against UV exposure even when wet. It tends to be more tightly woven, and some have special coatings to help absorb UV rays. These sun-protective clothes may have a label listing the UV protection factor (UPF) value – the level of protection the garment provides from the sun’s UV rays (on a scale from 15 to 50+). The higher the UPF, the higher the protection from UV rays. Some children’s swimsuits are now made from sun-protective fabric and are designed to cover the child from the neck to the knees.

Newer products, which are used in the washing machine like laundry detergents, can increase the UPF value of clothes you already own. They add a layer of UV protection to your clothes without changing the color or texture. This can be useful, but it’s not exactly clear how much it adds to protecting you from UV rays, so it is still important to follow the other steps listed here.

**Use sunscreen**

A sunscreen is a product that you apply to your skin for protection against the sun’s UV rays. But it’s important to know that sunscreen does not provide total protection against all UV rays. Therefore, a sunscreen should not be used as a way to prolong your time in the sun. Even with proper sunscreen use, some rays get through, which is why using other forms of sun protection is also important.

Sunscreens are available in many forms – lotions, creams, ointments, gels, sprays, wipes, and lip balms, to name a few.
Some cosmetics, such as lipsticks and foundations, also are considered sunscreen products if they contain sunscreen. Some makeup contains sunscreen, but only the label can tell you. Makeup, including lipstick, without sunscreen does not provide sun protection. Check the labels to find out.

**Read the labels**

When choosing a sunscreen product, be sure to read the label before you buy. Sunscreens with broad spectrum protection (against UVA and UVB rays) and with sun protection factor (SPF) values of 30 or higher are recommended. The SPF number is the level of protection the sunscreen provides against UVB rays – a higher number means more protection.

When using an SPF 30 sunscreen and applying it thickly, you get the equivalent of 1 minute of UVB rays for each 30 minutes you spend in the sun. So, 1 hour in the sun wearing SPF 30 sunscreen is the same as spending 2 minutes totally unprotected. People often do not apply enough sunscreen, so the actual protection they get is less.

Sunscreens labeled with SPFs as high as 100+ are now available. Higher numbers do mean more protection, but many people do not understand the SPF scale. SPF 15 sunscreens filter out about 93% of UVB rays, while SPF 30 sunscreens filter out about 97%, SPF 50 sunscreens about 98%, and SPF 100 about 99%. The higher you go, the smaller the difference becomes. No sunscreen protects you completely. Regardless of the SPF, sunscreen should be reapplied often for maximal protection.

The SPF number indicates protection against UVB rays only. Sunscreen products labeled “broad-spectrum” provide some protection against both UVA and UVB rays, but at this time there is no standard system for measuring protection from UVA rays. Products that contain avobenzene (Parsol 1789), ecamsule, zinc oxide, or titanium dioxide can provide some protection from UVB and most UVA rays.

Check the expiration date on the sunscreen container to be sure it is still effective. Most sunscreen products are effective for at least 2 to 3 years, but after a long time in storage you may need to shake the bottle to remix the sunscreen ingredients.

Some sunscreen products can irritate your skin. Many products claim to be hypoallergenic or dermatologist tested, but the only way to know for sure if a product will irritate your skin is to try it. One common recommendation is to apply a small amount to the soft skin on the inside of your elbow every day for 3 days. If your skin does not turn red or become itchy, the product is probably OK for you.

**Be sure to apply the sunscreen properly**

Always follow the label directions. Most recommend applying sunscreen generously. When putting it on, pay close attention to your face, ears, neck, arms, and any other areas not covered by clothing. If you’re going to wear insect repellent or makeup, put on the sunscreen first.

**Be generous**

Ideally, about 1 ounce of sunscreen (about a palmful) should be used to cover the arms, legs, neck, and face of the average adult. For best results, most sunscreens must be reapplied at least every 2 hours and even more often if you are swimming or sweating. Products labeled “waterproof” may
provide protection for at least 80 minutes even when you are swimming or sweating. Products that are “water resistant” may protect for only 40 minutes.

Remember that sunscreen usually rubs off when you towel yourself dry, so you will need to put more on.

Sunless tanning products, such as bronzers and extenders (described in the section, “What about tanning pills and other tanning products?”), give skin a tan or golden color. But unlike sunscreens, these products provide very little protection from UV damage.

**Wear a hat**

A hat with at least a 2- to 3-inch brim all around is ideal because it protects areas such as the ears, eyes, forehead, nose, and scalp that are often exposed to intense sun, such as the ears, eyes, forehead, nose, and scalp. A dark, non-reflective underside to the brim can also help lower the amount of UV rays reaching the face from reflective surfaces such as water. A shade cap (which looks like a baseball cap with about 7 inches of fabric draping down the sides and back) also is good, and will provide more protection for the neck. These are often sold in sports and outdoor supply stores.

A baseball cap protects the front and top of the head but not the neck or the ears, where skin cancers commonly develop. Straw hats are not as protective as hats made of tightly woven fabric.

**Wear sunglasses that block UV rays**

UV-blocking sunglasses are important for protecting the delicate skin around the eyes, as well as the eyes themselves. Research has shown that long hours in the sun without protecting your eyes increase your chances of developing some eye diseases.

The ideal sunglasses should block 99% to 100% of UVA and UVB radiation. Before you buy, check the label to make sure they do. Labels that say “UV absorption up to 400 nm” or “Meets ANSI UV Requirements” mean the glasses block at least 99% of UV rays. Those labeled “cosmetic” block about 70% of UV rays. If there is no label, don’t assume the sunglasses provide any UV protection.

Darker glasses are not necessarily better because UV protection comes from an invisible chemical applied to the lenses, not from the color or darkness of the lenses. Look for an ANSI label.

Large-framed and wraparound sunglasses are more likely to protect your eyes from light coming in from different angles. Children need smaller versions of real, protective adult sunglasses – not toy sunglasses.

Ideally, all types of eyewear, including prescription glasses and contact lenses, should absorb the entire UV spectrum. Some contact lenses are now made to block most UV rays. But because they don’t cover the whole eye and surrounding areas, they are not sufficient eye protection when used alone.

**Avoid tanning beds and sunlamps**

Many people believe the UV rays of tanning beds are harmless. This is not true. Tanning lamps give out UVA and usually UVB rays as well. Both UVA and UVB rays can cause long-term skin
damage, and can contribute to skin cancer. Tanning bed use has been linked with an increased risk of melanoma, especially if it is started before the age of 30. Most skin doctors and health organizations recommend not using tanning beds and sun lamps.

If you want a tan, one option is to use a sunless tanning lotion, which can provide a darker look without the danger (see the section, “What about tanning pills and other tanning products?”).

Protect children from the sun

Children need special attention, since they tend to spend more time outdoors, can burn more easily, and may not be aware of the dangers. Parents and other caregivers should protect children from excess sun exposure by using the steps above. Older children need to be cautioned about sun exposure as they become more independent. It is important, particularly in parts of the world where it is sunnier, to cover your children as fully as is reasonable. You should develop the habit of using sunscreen on exposed skin for yourself and your children whenever you go outdoors and may be exposed to large amounts of sunlight. If you or your child burns easily, be extra careful to cover up, limit exposure, and apply sunscreen.

Babies younger than 6 months should be kept out of direct sunlight and protected from the sun using hats and protective clothing. Sunscreen may be used on small areas of exposed skin only if adequate clothing and shade are not available.

A word about sun exposure and vitamin D

Doctors are learning that vitamin D has many health benefits. It might even help lower the risk for some cancers. Your skin makes vitamin D naturally when you are in the sun. How much vitamin D you make depends on many things, including how old you are, how dark your skin is, and how strong the sunlight is where you live.

At this time, doctors aren’t sure what the optimal level of vitamin D is. A lot of research is being done in this area. Whenever possible, it is better to get vitamin D from your diet or vitamin supplements rather than from sun exposure because dietary sources and vitamin supplements do not increase risk for skin cancer, and are typically more reliable ways to get the amount you need.

What about tanning pills and other tanning products?

Several products claim to give a tan without exposing a person to UV radiation. Some may be safe and effective, but others may not work, or may even be harmful.

Tanning pills and accelerators

Tanning pills contain color additives similar to beta-carotene, the substance that gives carrots their orange color. The additives are deposited throughout the body, especially the skin, turning it an orange-like color. Although the Food and Drug Administration (FDA) has approved some of these additives for coloring food, they are not approved for use in tanning agents. They may be harmful at the high levels that are consumed in tanning pills. The main ingredient in sunless tanning pills,
canthaxanthin, can show up in your eyes as yellow crystals, which may cause injury and impair vision. There have also been reports of liver and skin problems.

Tanning accelerators, such as lotions or pills that contain the amino acid tyrosine or its derivatives, are not effective and may be dangerous. Marketers promote these products as substances that stimulate the body’s own tanning process, but most evidence suggests they don’t work. The FDA considers them unapproved new drugs that have not been shown to be safe and effective.

**No tanning pills have been approved by the FDA.**

**Bronzers and extenders**

Two other sunless tanning products, bronzers and extenders, are considered cosmetics for external use and are not thought to be harmful when used properly.

Bronzers, made from color additives approved by the FDA for cosmetic use, stain the skin for a short time when applied and can be washed off with soap and water.

Extenders (also known as sunless tanners or self-tanners) are applied to the skin as lotions or creams, where they interact with proteins on the surface of the skin to produce a darker color. Like a tan, the color tends to wear off after a few days. The only FDA-approved color additive for extenders is dihydroxyacetone (DHA).

Applying these products by hand can sometimes lead to uneven coloring, so some tanning salons have begun to offer whole body sprays in tanning booths. A concern here is that DHA is approved for external use only and should not be inhaled or sprayed in or on the mouth, eyes, or nose. People who choose to get a DHA spray should make sure to protect these areas.

These products can give skin a darker color (although in some people it may have a slight orange tinge), but they don’t offer much protection from the damaging effects of UV radiation. Even if they contain sunscreen, it would only be effective for a couple of hours. You should read the label carefully to determine whether or not a product provides any protection, but in most cases it is safest to continue to use sunscreen and wear protective clothing when going outside.

**Skin exams**

Most skin cancers can be found early with skin exams. Both regular exams by your doctor and checking your own skin frequently can help find cancers early, when they are easier to treat.

**Get your skin checked by your doctor**

As part of a routine cancer-related checkup, your doctor should check your skin carefully. They should be willing to discuss any concerns you might have about this exam.

**Check your own skin**

It’s important to check your own skin, preferably once a month. A skin self-exam is best done in a well-lit room in front of a full-length mirror. You can use a hand-held mirror to look at areas that are hard to see. A spouse or close friend or family member may be able to help you with these exams, especially for those hard-to-see areas like your back or scalp.
The first time you examine your skin, spend time carefully going over the entire surface. Learn the pattern of moles, blemishes, freckles, and other marks on your skin so that you’ll notice any changes next time. Be sure to show your doctor any areas that concern you.

Follow these step-by-step instructions to examine your skin:

**Face the mirror**

Check your face, ears, neck, chest, and belly. Women will need to lift their breasts to check the skin underneath.

Check the underarm areas, both sides of your arms, the tops and bottoms of your hands, in between your fingers, and under your fingernails.

**Sit down**

Check the front of your thighs, shins, tops of your feet, in between your toes, and under your toenails.
You will need a hand mirror for the back of your legs and bottoms of your feet, as well as your back and scalp.

Now use a hand mirror to look at the bottoms of your feet, your calves, and the backs of your thighs, first checking one leg and then the other.

Use the hand mirror to check the buttocks, genital area, lower and upper back, and the back of the neck and ears. Or it may be easier to look at your back in the wall mirror using a hand mirror.

Use a comb or hair dryer to part your hair so that you can check your scalp.

What should I look for?

Skin cancers can show up in a variety of shapes and sizes. Be sure to show your doctor any abnormal areas that concern you, especially if they have just appeared or have changed recently.

Basal and squamous cell cancers

Basal cell cancers and squamous cell cancers are most often found in areas that get exposed to a lot of sun, such as the head, neck, and arms, but they can occur elsewhere. Look for new growths, spots, bumps, patches, or sores that don’t heal after several weeks.
**Basal cell carcinomas** often look like flat, firm, pale areas or small, raised, pink or red, translucent, shiny, pearly areas that may bleed after a minor injury. They may have one or more abnormal blood vessels, a lower area in their center, and blue, brown, or black areas. Large basal cell carcinomas may have oozing or crusted areas.

**Squamous cell carcinomas** may look like growing lumps, often with a rough, scaly, or crusted surface. They may also look like flat reddish patches in the skin that grow slowly.

Both of these types of skin cancer may develop as a flat area showing only slight changes from normal skin.

**Actinic keratosis**, also known as **solar keratosis**, is a skin condition that is sometimes precancerous and is caused by too much sun exposure. Actinic keratoses are usually small (less than ¼ inch across), rough spots that may be pink-red or flesh-colored. Usually they develop on the face, ears, backs of the hands, and arms of middle-aged or older people with fair skin, but they can occur in younger people or on other sun-exposed areas of the skin. People with one actinic keratosis usually develop many more. Some can grow into squamous cell cancers, but others may stay the same or even go away on their own. These areas should be looked at by a doctor, who can help determine if they should be treated.

**Moles and melanomas**

**Normal moles**

A normal mole is usually an evenly colored brown, tan, or black spot on the skin. It can be either flat or raised. It can be round or oval. Moles are generally less than 6 millimeters (about ¼ inch) across (about the width of a pencil eraser). A mole can be present at birth, or it can appear during childhood or young adulthood. New moles that appear later in life should be checked by a doctor.

Once a mole has developed, it will usually stay the same size, shape, and color for many years. Some moles may eventually fade away.

Most people have moles, and almost all moles are harmless. But it is important to recognize changes in a mole – such as in its size, shape, or color – that can suggest a melanoma may be developing.

**Possible signs of melanoma**

The most important warning sign for melanoma is a new spot on the skin or a spot that is changing in size, shape, or color. Another important sign is a spot that looks different from all of the other spots on your skin (known as the *ugly duckling sign*). If you have any of these warning signs, have your skin checked by a doctor.

The **ABCDE rule** is another guide to the usual signs of melanoma. Be on the lookout and tell your doctor about spots that have any of the following features:

- **A is for Asymmetry**: One half of a mole or birthmark does not match the other.
- **B is for Border**: The edges are irregular, ragged, notched, or blurred.
• **C is for Color:** The color is not the same all over and may include shades of brown or black, or sometimes with patches of pink, red, white, or blue.

• **D is for Diameter:** The spot is larger than 6 millimeters across (about ¼ inch – the size of a pencil eraser), although melanomas can sometimes be smaller than this.

• **E is for Evolving:** The mole is changing in size, shape, or color.

Some melanomas do not fit the rules described above, so it is important to tell your doctor about any changes or new spots on the skin, or growths that look different from the rest of your moles.

Other warning signs are:

• A sore that does not heal

• Spread of pigment from the border of a spot to surrounding skin

• Redness or a new swelling beyond the border

• Change in sensation – itchiness, tenderness, or pain

• Change in the surface of a mole – scaliness, oozing, bleeding, or the appearance of a bump or nodule

### What if I find something suspicious?

Be sure to show your doctor any area that concerns you. A qualified doctor should be able to identify any suspicious areas you may have. If your doctor suspects you might have skin cancer, he or she will use one or more of the following methods to find out.

#### Medical history and physical exam

Usually the doctor’s first step is to take your medical history. The doctor will ask when the mark on the skin first appeared, if it has changed in size or appearance, and if it has caused any symptoms (pain, itching, bleeding, etc.). You could also be asked about past exposures to causes of skin cancer (including sunburns and tanning practices) and if you or anyone in your family has had skin cancer.

During your physical exam, your doctor will note the size, shape, color, and texture of the area in question, and if there is bleeding or scaling. The rest of your body may be checked for spots and moles that could be related to skin cancer.

The doctor may also feel the lymph nodes (bean-sized collections of immune system cells) under the skin near the suspicious area. Some skin cancers may spread to lymph nodes. When this happens, the affected lymph nodes may become larger and firmer than usual.

If you are being seen by your primary doctor and skin cancer is suspected, you may be referred to a dermatologist (a doctor who specializes in skin diseases), who will look at the area more closely.

Along with a standard physical exam, many dermatologists use dermoscopy (also known as epiluminescence microscopy [ELM], surface microscopy, or dermatoscopy) to see spots on the skin more clearly. The doctor uses a dermatoscope, which is a special magnifying lens and light
source held near the skin. Sometimes the doctor will use a thin layer of oil with this instrument. A digital or photographic image of the spot may be taken. The doctor may take a digital photo of the spot.

When used by an experienced dermatologist, this test can improve the accuracy of finding skin cancers early. It can also often help reassure you if a spot on the skin is likely benign (non-cancerous) without the need for a biopsy.

Skin biopsy

If the doctor thinks that a suspicious area might be skin cancer, they will remove a sample of skin from that area to be looked at under a microscope. This is called a skin biopsy. Different methods can be used for a skin biopsy. The doctor will choose one based on the suspected type of skin cancer, where it is on the body, the size of the affected area, and other factors. For more detailed information on biopsies, see our documents, *Melanoma Skin Cancer* and *Skin Cancer: Basal and Squamous Cell*.

If a spot is found to be cancerous or pre-cancerous, your doctor may recommend further tests or treatment. If the spot is small and localized, a more extensive biopsy or some type of surgery may be all that is needed. For cancers that might be more extensive (especially melanomas), imaging tests might be done to see if the cancer has spread, and further treatment such as immunotherapy, targeted therapy, chemotherapy, or radiation might be needed. Again, for more detailed information, see our skin cancer documents.
